Executive Summary

This deliverable consists of a software deliverable of the highly available Hadoop Filesystem (HDFS), a userguide for the software, and a short description of the system's architecture.

Our implementation of HDFS provides a new distributed model for HDFS' metadata, based on storing the metadata in MySQL Cluster, a distributed, in-memory, highly available relational database. Our implementation strengthens the replication model of HDFS v2, which is based on eventually consistent primary-secondary replication, to one of shared atomic memory, thus simplifying some of HDFS' internal protocols and enabling support for many NameNodes (as opposed to only a primary and secondary NameNode in HDFS v2). Our implementation also maintains the consistency semantics of HDFS, and we validate this by ensuring that all 300+ unit tests for HDFS pass.

This deliverable also describes the platform-as-a-service (PaaS) support we provide for our HDFS implementation. Our HDFS implementation, along with Apache YARN, can be easily installed by unsophisticated users by just pointing and clicking from our portal website to any of the following platforms: Amazon Web Services, OpenStack or a cluster of (bare-metal) hosts. We also provide a Dashboard to administer and monitor the deployed Hadoop cluster.

The document is structured as a userguide for installing and managing a Hadoop platform containing our highly available HDFS distribution, followed by a brief description of the system architecture.

The code is available for download now, although it is still very much beta and under heavy development.

Chapter 1. Hop Architecture

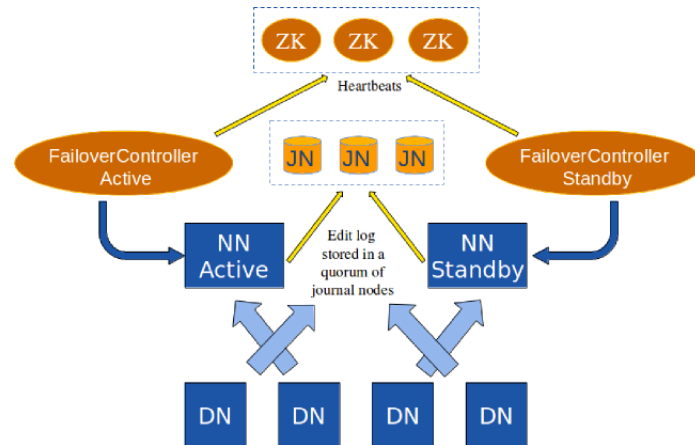

Highly Available Hadoop Filesystem (HDFS)

Due to the rapid growth of data in recent years, distributed file systems have gained widespread adoption. The new breed of distributed file systems reliably store petabytes of data, and also provide rich abstractions for massively parallel data analytics. The Hadoop Distributed File System (HDFS) is a distributed, fault-tolerant file system designed to run on low-cost commodity hardware that scales to store petabytes of data, and is the file storage component of the Hadoop platform. HDFS provides the storage layer for MapReduce, Hive, HBase, Spark and all other YARN applications, see Figure 1.1, “Hadoop v2”.

Figure 1.1. Hadoop v2

In 2013, HDFS v2 introduced a new highly available metadata architecture, where, as in HDFS v1, the entire filesystem's metadata is stored in memory on a single node, but in v2 changes to the metadata (*edit log entries*) are now replicated and persisted to a set of (at least three) Journal Nodes using a quorum-based replication algorithm. In HDFS v2, a Primary and Secondary NameNode can be configured, where the Primary NameNode is responsible for managing the metadata, and the Secondary NameNode keeps an eventually consistent copy of the metadata. The Secondary NameNode is kept in sync with the Primary by two mechanisms: firstly, by asynchronously applying all edit log entries that have been committed at the Journal Nodes, and secondly, receiving the same set of heartbeats from Data Nodes that are received by the Primary. The Primary/Secondary replication model is also known as an Active/Standby or Master/Slave replication model, and was popularized by databases in the 1990s. HDFS' implementation of this eventually consistent replication model is more limited than in the traditional relational database world, as all read and write requests are sent to the Primary. In typical Master/Slave configurations, writes are sent to the master, while reads are load-balanced across slaves. The reason all write requests are sent to the Primary to ensure a single consistent copy of the metadata. Read requests are also sent to the Primary, as reads at the Secondary could result in operations being executed on stale metadata. This is a bigger problem for a filesystem, such as HDFS, than it would be for a Web 2.0 social media application with non-critical data, using a Master/Slave database setup. Thus, reads are only sent to the Primary. If the Primary fails, however, the Secondary needs to take over as Primary. Before it can take over, it first has to catch up with the set of edit log entries applied to Primary before it failed. The period of time before all outstanding edit log entries are applied at the Secondary before it can take over may be up to tens of seconds, depending on the current load of the system and the hardware and software setup. Another limitation of the Primary/Secondary model, is that client and Data Nodes from HDFS need to have a consistent view of who the current Primary NameNode is. They do this by asking a Zookeeper coordination service that needs to run on at least 3 nodes to provide a fault tolerant reliable service. Finally, the concurrency model supported by HDFS v2 is still multiple-readers, single-writer.

Figure 1.2. HDFS v2 NameNode Primary/Secondary Replication Model

In contrast, our implementation of HDFS, called Hop HDFS, replaces the Primary-Secondary metadata model with shared, transactional memory, implemented using a distributed, in-memory, shared-nothing database, MySQL Cluster, see figure Figure 1.3, “Hop HDFS”. In our new model, the size of HDFS' metadata is no longer limited to the amount of memory that can be managed on the JVM of a single node. Our solution involves storing the metadata in a replicated, distributed, in-memory database that can scale up to several tens of nodes, all while maintaining the consistency semantics of HDFS. We maintain the consistency of the metadata, while providing high performance, all within a multiple-writer, multiple-reader concurrency model. Multiple concurrent writers are now supported for the filesystem as a whole, but single-writer concurrency is enforced at the inode level. Our solution guarantees freedom from deadlock and progress by logically organizing inodes (and their constituent blocks and replicas) into a hierarchy and having transactions defining on a global order for transactions acquiring both explicit locks and implicit locks on subtrees in the hierarchy. The use of a database, however, also has its drawbacks. As the data now resides on remote hosts on the network, an excessive number of roundtrips to the database harms system scalability and increases per-operation latencies. We ameliorate these problems by introducing a snapshotting mechanism for transactions, where, at the beginning of a transaction, all the resources it needs are acquired in the defined global order, while simultaneously taking row-level locks for those resources. On transaction commit or abort, the resources are freed. This solution enables NameNodes to perform operations on a local copy (or snapshot) of the transactions state until such time as the transaction is completed, thus reducing the number the number of roundtrips to the database, see Figure 1.4, “Reduction in the DB roundtrips by snapshotting metadata at the NameNodes”.

Figure 1.3. Hop HDFS

Early performance measurements for Hop HDFS

Our early performance figures show that Hop HDFS can scale to handle a similar number of read and write requests per unit time as Apache HDFS. We have introduced a number of features to enable this high level of performance, including a snapshot layer at NameNodes and row-level locking at the database level, rather than a system level lock for update operations as is done in Apache HDFS. Our snapshotting layer involves a transaction acquiring all resources it requires at the start of a primitive filesystem operation, and performing local read/write operations on the snapshot copy, and then finally committing or rolling back on transaction commit.

Figure 1.4. Reduction in the DB roundtrips by snapshotting metadata at the NameNodes

Hop Architecture

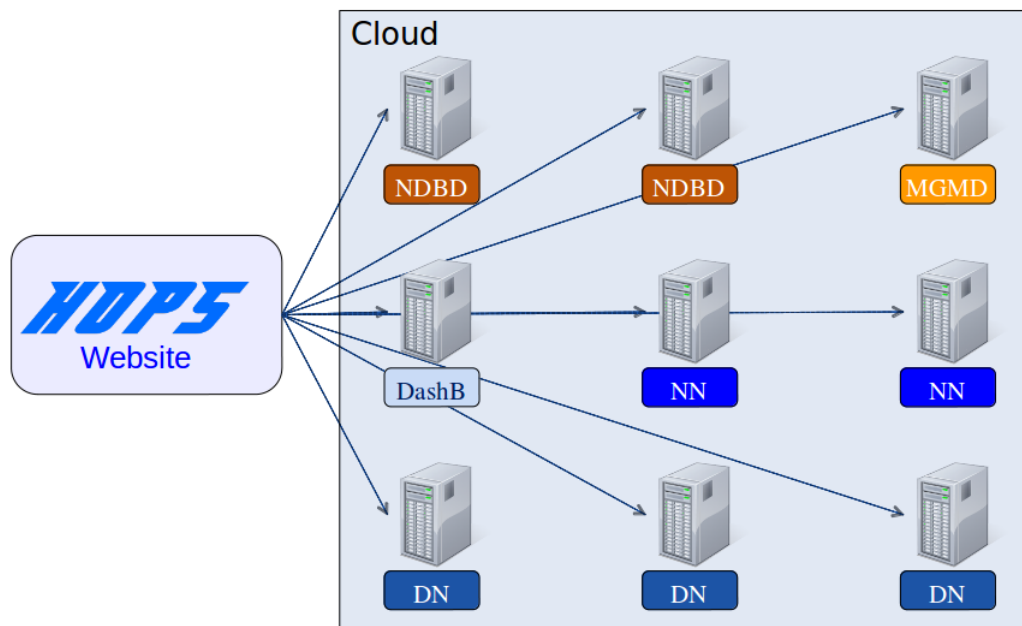

Hops, as a cloud platform for distributed processing and big data, is made up of latest Hadoop ecosystem. As you can see in Figure 1.5, "Hop stack" there are three major layers in our stack, HDFS, YARN and Workflow. Cross-layer aspects like Security and PaaS services are also included.

Figure 1.5. Hop stack

1. *HOP File System (HOP-FS)* At the bottom layer of big data stack is HOP-FS a distributed file system based on Hadoop Distributed File System (HDFS). We revisited relational representation of metadata to remove limitation of single metadata server and single point of failure. Our File System solution can scale up to several tens of nodes, while maintaining the consistency semantics for the filesystem. We store the metadata on a shared-nothing, in-memory, partitioned database by maintaining the consistency of the metadata, while providing high performance. HOP-FS also guarantees freedom from deadlock and progress.
2. *MySQL Cluster* MySQL Cluster is a highly scalable, real-time, ACID-complaint transactional database. Designed around a distributed, multi-master architecture with no single point of failure; MySQL Cluster's real-time design delivers predictable, milisecond response times with the ability to service millions of operations per second. In the case of our data platform, it is used to handle and manage the state of our multi-namenode solution of our architecture.
3. *YARN* Resource negotiator for managing high volume distributed data processing tasks against HDFS. It supports different processing models other that Map-Reduce by separating its Resource Manager from Scheduler and Application Master. Application Master gives us flexibility to accommodate heterogeneous processes by implementing a wrapper for each kind of application so it could manage any kind of processing resources that is defined for it. This allows user to process data intensive task like MapReduce jobs or in our case our future support for bioinformatic workflow tasks engine which will make use of YARN to handle and negotiate the scheduling of this type of jobs.
4. *Workflow Engine* On top of YARN, HOPS workflow engine parses workflows into an execution model of arbitrary tasks. For each task, it asks YARN for a container, then for each container allocated task based on the scheduling policy it stages in data into HOPSFS, launches the task and stages out the result back to HOPSFS

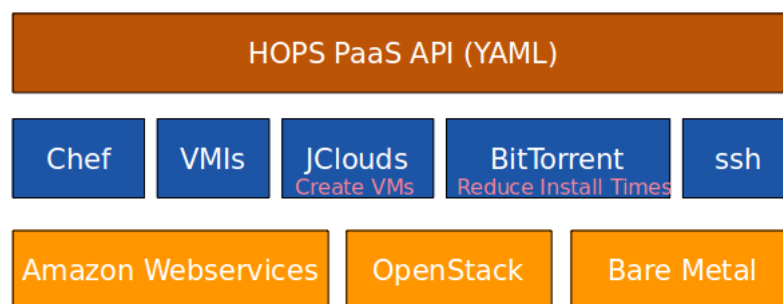

Deployment model

At the moment HOPS supports Amazon Cloud, Open Stack and Bare Metal. Based on the chosen cloud provider, as it can be seen in Figure 1.6, "Deployment Model" our deployment model consist of Hops-Dashboard plus other machines either virtual in cloud or bare metal. Dashboard is the point of administration with web access through which customer could define configuration of the cluster, machines are allocated, their software stack is installed and state of the cluster is monitored. Cloud machines could be associated into security node-groups, machines inside each node-group basically have the same security credentials and could communicate with each other; however, communication between machnies from different security group is not possible. All the machins inside the cluster have the same infrastructure and basic stack of softwares, althoug based on the services each machine shoul provide, arbitrary platform softwares are installed.

Figure 1.6. Deployment Model

HDFS Platform-as-a-Service

Our Platform-as-a-Service model describes the set of frameworks and tools that we use to deploy a Hadoop cluster on both cloud and bare-metal clusters.

Figure 1.7. Hop PaaS

Hop PaaS Stack

1. *SnakeYAML and YAML* YAML (YAML Ain't Markup Language) is markup language which takes concepts from programming languages such as C, Perl and Python, and ideas from XML. YAML syntax allows easy mappings of common data types found in high level languages like list, associative arrays and scalar. It makes it suitable for tasks where humans are likely to view or edit data structures, such as configuration files or in our case, cluster definition files. Additionally, we make use of the open source parser SnakeYAML to parse the contents of our cluster definition files. Parser transforms the given cluster definition into consecutive stages such as defining security groups, virtual machine allocation, bittorrent, installation, validation and retry.
2. *Apache JClouds* Apache JClouds is an open source multi-api interface which allows easy interaction with multiple cloud providers and cloud software stacks. This open source api gives support around 30 providers which include Amazon, Azure, OpenStack and Rackspace. JClouds offers api implementations both in Java or Clojure. Through they simple interface, it is very simple to deploy and port your application over different cloud environments. Each single configuration in YAML may result in multiple JCloud instructions.

3. *Chef* Chef is a systems and cloud infrastructure automation framework based on Ruby that simplifies deployment of servers and applications to any physical, virtual or cloud location no matter the size of the infrastructure. The chef-client relies in a series of abstract definitions (defined as cookbooks and recopes) which are managed in Ruby and are treated like source code. With each definition, we describe how a specific part should be built and managed, which then; the chef-client applies these definitions to deploy and configure servers and applications as specified. In most of the cases, it is simple enough to let chef-client know which cookbooks and recipes it needs to apply.
4. *BitTorrent* After machines are allocated in cloud, with the metadata information that JCloud returns, dashboard tries to open a ssh connection into every single machine and install Chef agent for installations. Before installation starts, software libraries is replicated in all machines from dashboard, though the process could overflow the bandwidth to dashboard if all machines try to download from dashboard. To handle this situation HOPS run a bittorrent in which dashboard machine is the seeder, then all machnies could contribute to download process which is both faster and anti-bottleneck. After download Chef agent starts installation based on the required packages in each machine and with the order of dependencies between packages.

Chapter 2. Quickstart with Vagrant

This section describes the steps required to deploy a HOP cluster on a single machine using git, vagrant¹, and chef².

Pre-requisites:

You should have the following programs installed: git and vagrant. You will also need to download the vagrant virtual machine image for Ubuntu 12.04 "precise".

```
apt-get install git-core vagrant
vagrant box add "precise64" http://files.vagrantup.com/precise64.box
```

Launching Vagrant

You are ready to clone the chef recipes, and launch a vagrant instance.

```
git clone https://github.com/hopstart/hop-chef.git
cd hop-chef
vagrant up
```

Now grab a coffee, assuming you have a good network connection, it will take around 15 minutes to provision a vagrant instance. When vagrant successfully completes provisioning using chef, use the following URL and default user credentials to access the Hop Dashboard:

```
https://localhost:9191/hops-dashboard/
user: admin
password: admin
```

You can log into the VM and then get root access using:

```
vagrant ssh
sudo su
```

If needed, you can configure the glassfish webserver here:

```
https://localhost:5858
user: admin
password: admin
```

You can now jump to Chapter 4, *Dashboard*

¹ Vagrant is a tool for building complete development environments. With an easy-to-use workflow and focus on automation, Vagrant lowers development environment setup time, increases development/production parity, and makes the "works on my machine" excuse a relic of the past. [http://www.vagrantup.com]

² Chef is a systems and cloud infrastructure automation framework that makes it easy to deploy servers and applications to any physical, virtual, or cloud location, no matter the size of the infrastructure. [http://docs.opscode.com/]

Chapter 3. Portal

Hadoop Open Platform-as-a-service (HOP) is an effort to offer a high performance next generation hadoop platform focusing on high scalability, availability and reliability. This section describes the information needed to start HOP cluster using the Dashboard application. HOP Dashboard provides a centralized end-to-end management and monitoring application for HOP distribution operating in a datacenter of your choice i.e. AWS, OpenStack and Baremetal Machines. Using HOP Dashboard's graphical user interface (GUI) you can define, monitor and manage your clusters in the data centres.

Example 3.1. HOP Portal

`https://snurran.sics.se:8181/hop-portal`

Figure 3.1. Hop Portal

The image shows a web browser window with the title "Hadoop Open PaaS Portal". The main content area is a light gray box with the heading "Sign in". Below the heading are two input fields: "Username" and "Password", both with yellow backgrounds. To the right of the "Password" field is a blue button with the text "Sign in".

Requirements:

In order to make use of our data platform, it is essential that you have a running a copy of our dashboard application running in your main machine through one of the supported environments we offer, and has connectivity both to the rest of your cluster or cloud Infrastructure. For ease of use, we currently have available our own web portal, that in matter of minutes, will deploy our dashboard. For now, the supported OS in our test bed was Ubuntu 12.04 or higher. The following environments are currently fully supported:

- *Amazon Web Services:* In order to use of our platform in AWS cloud Infrastructure, it is necessary to provide EC2 account credentials. When deploying our Dashboard in EC2, we recommend minimum Instance type should be of m1.large type Instance with Ubuntu (our default test bed used version 12.04).
- *OpenStack* For using HOP on OpenStack, it is necessary that you provide the credentials and configuration parameters to connect to you OpenStack end-point. The recommended instance to use in OpenStack infrastructure should be equivalent to a m1.large instance type or greater with an Ubuntu based image (our default test bed used ubuntu 12.04 cloud guest edition).
- *Baremetal Physical Machine:* For deployment on Baremetal machines our system requires security credentials of a user with sudo access to the machines to deploy the software through SSH . The recommended OS for deploying is Ubuntu (our default test bed used ubuntu 12.04).

- *Vagrant*: With our vagrant distribution, you can deploy the whole cluster locally in a VM machine. Ideal for testing the platform before deployment in a production environment.

HOP Portal

HOP web portal, is an entry point where users can test our platform in one of our supported environments. It is a simple web application that can deploy the HOP dashboard in AWS or in a private cloud with external connectivity. Using the HOP dashboard you can deploy and configure the rest of the cluster. Following are the step by step instructions for setting up the cluster in different environments.

How to launch a HOP Dashboard

Launching a HOP Dashboard is quite simple and takes a couple of minutes to deploy. Here you may find instructions on how to use the dashboard for Amazon EC2 and Baremetal Machine:

1. *Amazon EC2*: In order to deploy our dashboard in Amazon EC2 in the region of your choice follow these simple steps:

- Login into the HOP Portal with your user name and password.
- Select from the providers option in the maintoolbar, the Amazon EC2 option. A form will be generated
 - Dashboard credential, where you specify the admin username and password in order to access your newly created dashboard.
 - EC2 credentials which include the Access Key id from your AWS account with its related Secret key.
 - Instance configuration parameters that we need in order to deploy a virtual machine in Amazon with default values that you may want to change:
 - a. Security group where the machine will be deployed. If it does not exist, then a new security group will be created automatically.
 - b. The hardware ID of the instance type we want to use from Amazon EC2. For example, m1.small, t1.micro. The recommended instance type is m1.large.
 - c. Image ID which includes the region of that image and the ami id tag. We only support Ubuntu based images.
 - d. Location ID of the region you want to deploy the dashboard.
 - e. Selecting the option to authorize the public key, it will open a new option dialog box where you can insert your desired public key so that you can access the virtual machines. By default we generate random key pairs for the machines through EC2 key pair service, and it is not possible to access the machines internally without this option.
 - f. Selecting the override login user, will override the default user for Ubuntu AMI images with the login user of your choice. This is necessary if you are going to use a custom Ubuntu images which are not one of the Ubuntu images that canonical offer in AWS by default.

Figure 3.2. Portal AWS

Select Provider: Amazon-EC2

Create Dashboard

Dashboard Credentials

Provider: Amazon-EC2

Username *: Username for dashboard user

Password *: Password for dashboard user

Provider Login Credentials

id *: Access Key Id from AWS

Secret Key: Secret Access Key for AWS

Instance Parameters

Security Group Name *: hops

Hardware ID: *: m1.large

Image ID: *: eu-west-1/ami-ffdcce8b

Location ID: eu-west-1

Enable Authorize Public Key: *

Override Login User: *

Launch Instance

- To start the process after filling up the form, press the launch instance button. The whole process will probably take between 10-15 minutes on average. In the end, you will receive a notification showing the address where you can access the Dashboard in your browser and its private ip address. To login, use the credentials you specified previously in the portal.
2. *OpenStack*: In order to deploy our dashboard in OpenStack follow these simple steps. Note, this is in alpha state:
- Login into the HOP Portal with your user name and password.
 - In the new page, select from the providers the Amazon EC2 option. A form will be generated.
 - Dashboard credentials: here you specify the admin username and password in order to access your newly created dashboard.
 - OpenStack credentials: the user name and password to access the OpenStack project. The username should be a concatenation of the OpenStack project name and the user for that project. For example "projectName:user". Also you should indicate the url of your OpenStack Nova end-point in order to send the requests to your OpenStack infrastructure.
 - Configuration parameters that we need to in order to deploy a virtual machine in OpenStack with default values that you may want to change:
 - a. Security group where the machine will be deployed. If it does not exist, we will create it and open the ports needed for our application.

- b. The hardware ID of the instance type we want to use in OpenStack. This is a number which corresponds to the type of instance you want to deploy and is supported by your OpenStack infrastructure. We recommended using a configuration similar to a m1.large in EC2.
- c. Image ID corresponding to the id of the image located in the openstack project you want to deploy the dashboard.
- d. Location ID of the project you want to deploy the dashboard.
- e. Selecting the option to authorize the public key, it will open a new option were you can insert your desired public key so you can access the virtual machine. By default we generate random key pairs for the machine through OpenStack key pair service, and it is not possible to access the machine internally without selecting this option.
- f. Selecting the override login user: This is necessary for OpenStack if you are going to use a custom based ubuntu image.

Launch Instance

- To start the process after filling up the form, press the launch instance button. On average the whole process will probably take between 10-15 minutes. In the end, you will receive a notification showing the address were you can access the Dashboard in your browser and its private ip address. To login, use the credentials you specified previously in the portal.

IP pools in OpenStack

In order to deploy successfully the dashboard in OpenStack, it is necessary that you have allocated at least 1 public IP in that project. During the deployment phase we will query the OpenStack project and link the public ip to the VM.

3. *Baremetal Physical Machine*: In order to deploy our dashboard in a physical machines follow these simple steps:
 - Login into the Hop Portal with your user name and password.
 - In the new page, select Amazon EC2 from the providers list. A form will be generated were you need to fill in the following:
 - Dashboard credentials: were you specify the admin username and password in order to access your newly created dashboard.
 - SSH credentials: which include the host address of the machine we want to connect to and the private key to connect.
 - Extra parameters that we might need:
 - a. Selecting the option to authorize the public key, it will open a new option were you can insert your desired public key to allow extra access to the machine.
 - b. Selecting the override login user, here you fill the name of the sudo user to use to deploy our dashboard on the machine.

Launch Instance

- To start the process after filling up the form, press the launch instance button. The whole process will probably take between 10-15 minutes. In the end, you will receive a notification showing the address where you can access the Dashboard in your browser and its private ip address. To login, use the credentials you specified previously in the portal.

Chapter 4. Dashboard

In this section we will give an overview of our HOP Dashboard web based application. This web application is design with Hadoop administrators in mind so they can easily monitor, define and maintain HOP cluster through an endpoint. This simplifies Hadoop administrator's job by having all the necessary information of the hadoop cluster gathered in one place and presented in an effective manner. Also it is possible to execute maintanance commands through the different terminals available for services like MySQL, HDFS or Spark.

When you launch the HOP Dashboard for the first time, you will need to configure some parameters to get starting with Hop. In order to access the dashboard, use the credentials you specified in the Hop Portal when you where preparing to launch the dashboard Chapter 3, *Portal*. After login, if you press your user icon you will have a menu with the following options:

- Change password
- Edit Graphs
- Backup/Restore
- Setup Credentials

We will go over this options in detail in the following sections.

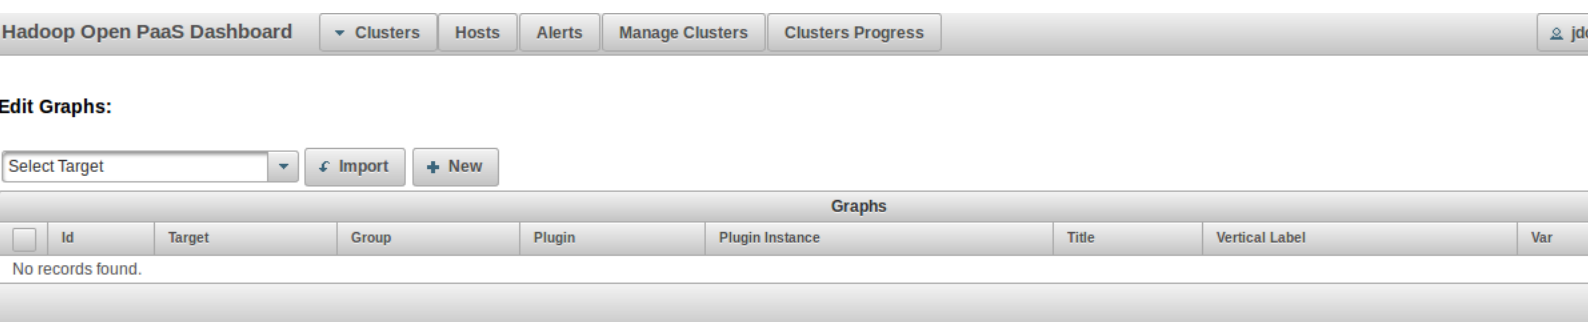

Change Password

This option will give the user the functionality to change their password if they need to do it. For now this functionality is not implemented.

Edit Graphs

Hop Dashboard offers great customization of how you want to display the data retrieved from the Hop agents allocated in each one of the nodes that make up your cluster. Selecting this option will bring you to a new view where you can define the graphs for the different services of Hop.

Figure 4.1. Edit Graphs

You can define your graphs through two different options that are visible on this new view:

- *New* Selecting this option will open a new dialog where you can define the main specifications of your graph for a certain type of element monitored by the dashboard.

- *Import* It is also possible to import the graphs from a graph file written in JSON, this is the quickest way if you want to load a large number of graphs

Figure 4.3. Import Graphs

When graphs are generated, they are stored in the graph database and loaded in the dashboard. In the graph tables, it is possible to view all the graphs for a specific type of service or component the dashboard is capable of monitoring. Choosing an entry with the zoom icon, will generate a dialog box where you can see more details of the graph entry.

Figure 4.4. Graph Selection Detail

Backup/Restore

The Backup/Restore option allows the user to do 2 things, one is to do a whole backup of the dashboard state stored in the database in case of failure, maintenance or any other reasons. The other option is to restore the dashboard's state from a previous backup which was obtained from the dashboard.

Figure 4.5. Backup/Restore

The screenshot shows the 'Hadoop Open PaaS Dashboard' with a navigation bar containing 'Clusters', 'Hosts', 'Alerts', 'Manage Clusters', and 'Clusters Progress'. The user 'jdowling@sics.se' is logged in. The main content area is titled 'Backup / Restore Database' and contains two sections: 'Backup Database' and 'Restore Database'. The 'Backup Database' section has the text 'Backup the database and download the backup file:' and a 'Download Backup File' button. The 'Restore Database' section has the text 'Upload backup file and restore the database:' and an 'Upload and Restore' button with a plus icon.

Setup Credentials

This option allows the user to setup the credentials that will be used when the dashboard deploys a cluster. You can select between Amazon EC2, OpenStack or Baremetal, depending on what option you select; it will enable or disable sections of the form. This is important as not setting up this credentials, will make the deployment architecture to fail when querying the cloud providers for the necessary resources for your clusters.

Cluster Management

One of the options in the main Dashboard toolbar which will be of interest for Hadoop Administrators is the Manage Cluster option. This will bring a new view where users will be able to do a series of basic operations with their stored clusters. The Dashboard will keep track of all the users clusters in a table that will be visible when the user accesses this view. Also in this view, users are able to upload clusters easily with the provided uploader. In the next chapter, we will explain in detail how users can create their clusters using our cluster definition language or the provided cluster generator wizard, see Chapter 5, *Defining a Cluster*.

Figure 4.7. Manage Cluster**Cluster Management:**

You can load from a cluster definition file No file selected.

You can also select a cluster from the database

Available cluster configurations		
Cluster Name	Cluster Type	Content
test2	virtualized	prod,aws-ec2,eu-west-1
test	virtualized	dev,aws-ec2,eu-west-1
<input type="button" value="+ Create Cluster"/> <input type="button" value="- Delete clusters"/> <input type="button" value="Edit selected cluster"/> <input type="button" value="Load selected cluster"/> <input type="button" value="Export selected cluster"/>		

From the previous image we can see that the following options are available for a user:

- *Create Cluster* Selecting this option it will take you to the cluster generation wizard where a user will be capable of generating its own cluster for HOP. We will explain in detail how this process works in the next chapter Chapter 5, *Defining a Cluster*.
- *Delete Clusters* This option will delete a selected cluster from the table. It is possible to delete multiple entries at once by shift clicking multiple entries before selecting this option.
- *Edit Selected Cluster* This option will allow a user to edit an existing cluster from the stored clusters. This will bring the cluster generation wizard with the values of the selected cluster so the user can modify their cluster.
- *Load Selected Cluster* This option will allow the user to load one of the stored clusters into the cluster launcher. From there the user can deploy the cluster on the environment of defined in that cluster.
- *Export Cluster* This option allows the user to download, in a YAML file; a stored cluster in the dashboard.

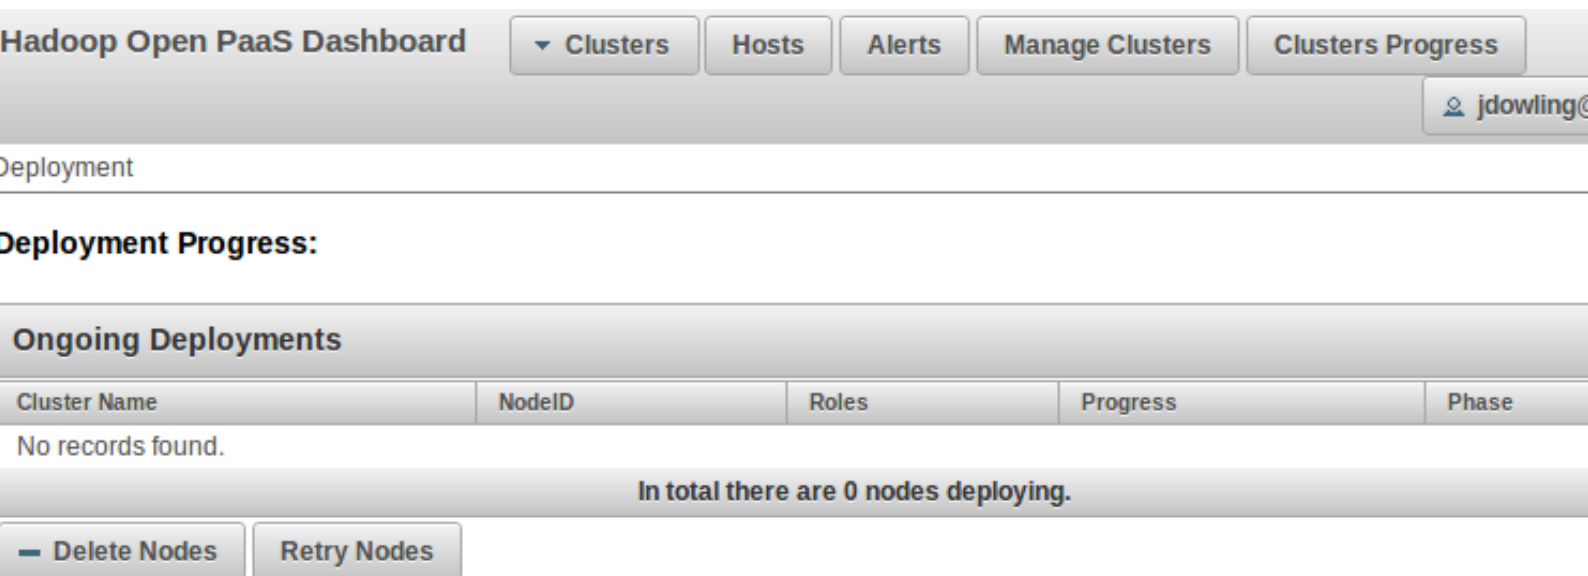

Clusters Progress

Another interesting feature for Hadoop administrators, is the option available in the main Dashboard toolbar for tracking the progress of the nodes deployed for your multiple clusters. Selecting this option will bring you a view where you will have all the history of all the nodes through multiple phases of the deployment cycle. A progress bar will appear over each of the entries in the table to see the deployment progress of the nodes and an information tag with the current phase. Here you will be notified of successfully configured nodes or nodes that had an error during the deployment phase of your cluster which will require of special maintenance. A node entry will go through the following phases during a cluster deployment.

- *Waiting* A node in this phase means, that; the entry has been generated in the node scheduler but no node creation query has been generated to the cloud provider. It will wait until the query is submitted against the cloud provider.
- *Creation* A node in this phase means, that; the scheduler has submitted the query against the cloud provider and it is waiting for the cloud provider to finish deploying the virtual instance. After successfully getting back the information of the specific instance, an initialization script is executed to do a preliminary configuration on that node.

- *Install* A node in this phase means, that; the node is already created and we are running the install script which will execute chef install recipes for Hop services to fetch the necessary binaries from the different repositories. This phase is optional in case of using prebuilt virtual instances which contain Hop binaries inside.
- *Configure* A node in this phase means, that; the node is receiving the configuration script which will execute chef with the selected recipes for the services defined for that node.
- *Complete* A node in this phase means, that; the node has successfully finished executing the configuration script with chef and it is now working as part of the cluster. Additionally, the nodes in this phase will appear green in the progress history.
- *Retrying* A node in this phase means, that; the deployment system has detected a problem during a previous node phase and it is triggering the retrying mechanism. It will retry submitting the previous phase script for 5 retries. This process ends when the number of retries finish or we manage to successfully execute the script.
- *Error* A node in this phase means, that; the deployment system failed to recover the node through the retrying mechanism. This will be shown as a Red entry in the progress table and further actions will be needed by the Hadoop administrator in order to recover that node, for example; SSH to the failed node in order to get more information of the type of error it got.

Figure 4.8. Clusters Progress

From the previous figure, we get an overview of the cluster progress table. In here, the user is capable of executing the following actions:

- *Delete Nodes* A user can select multiple node entries by shift click and later delete their progress history by executing this command. Note that this option will delete node entries which are registered with a node complete phase.
- *Retry Nodes* A user can do make use of this option in order to execute further retry procedures on nodes that failed to deploy correctly. This will make the deployment system to execute a recovery script on the selected nodes in an error state. For now, this script simply tries to rerun the nodes configuration script by executing only chef in that node. It is possible to retry multiple nodes at once by selecting multiple entries by shift click.

Monitoring

The Hop Dashboard offers multiple ways in how you can monitor the state of your current Hop clusters. The following options related to monitoring features can be found in the main Dashboard toolbar

- *Hosts* Information and data analytics of all the nodes this dashboard is monitoring.
- *Alerts* Information of possible alerts the Hop agents will be sending the dashboard in order to notify the current state of the nodes.
- *Clusters* A dropdown list with the available clusters been monitored by the dashboard. Selecting an entry will give further information of the state of that cluster.

Hosts

This view allows a user to get a general overview of the state of all the nodes in all the clusters, you will be able to track information of great interest like the allocated ip's for that node, its hostname, host ID, its current health in the system, and when the last heartbeat was received. Also it shows information about the nodes available resources like the number of cores that machine has, the load average in that instance in the last 1, 5 15 min, disk usage and physical memory in use.

Alerts

This view allows a user to keep track of the whole history of alerts submitted by the Hop agents. Here you will see for each entry an alert submitted by one of the agents containing the message provided by that alert plus the date the message was generated, the severity of the alert and the host ID that triggered the alert. Also further information is provided with the alert like the source that originated the alert and other parameters that help to track the source of the alert.

Clusters

Selecting this option from the main Dashboard toolbar, will generate a dropdown list with all the available clusters been actually monitored by the dashboard. From here you can navigate and get further detail of the cluster and the current status of the services running in that cluster. This allows a user to navigate through the different Hop services and sub roles allowing the user to grasp a deep understanding of what is currently going on each of the services.

Figure 4.13. Clusters

The screenshot shows the 'Hadoop Open PaaS Dashboard' with a navigation bar containing 'Clusters', 'Hosts', 'Alerts', 'Manage Clusters', and 'Clusters Progress'. A dropdown menu is open under 'Clusters', showing 'All Clusters' and 'vagrant'. Below the menu, the 'Cluster Under Management:' section is visible. The main table, titled 'Clusters', has columns: Cluster name, Services, Roles, Roles Status, Health, Hosts, Cores, Disk Capacity, Memory Capacity, and Actions. The 'vagrant' cluster is listed with services 'MySQLCluster', 'HOPS', and 'YARN'. Its roles include '1 mgmserver', '1 memcached', '1 namenode', '1 ndb', '1 NodeManager', and '1 datanode'. The roles status is '8 Started', health is 'Good', it has 1 host, 2 cores, 78.9 GB disk capacity, and 3.8 GB memory capacity.

Cluster name	Services	Roles	Roles Status	Health	Hosts	Cores	Disk Capacity	Memory Capacity	Actions
vagrant	MySQLCluster HOPS YARN	1 mgmserver 1 memcached 1 namenode 1 ndb 1 NodeManager 1 datanode 1 mysqlid 1 ResourceManager	8 Started	Good	1	2	78.9 GB	3.8 GB	

From the previous image, we can see a top level overview of each cluster with general information on the status of that cluster. This contains information on the number of nodes that compose that cluster, the current health of the cluster and the number of hosts involved in the cluster. Also it keeps track of the resources allocated on that cluster like the total number of cores which compose the overall computing power of the cluster, the total disk capacity and the total physical memory capacity. Selecting a cluster entry will bring a more detailed view of that cluster.

Figure 4.14. Cluster Detail

The screenshot shows the 'Cluster Detail' view for the 'vagrant' cluster. The navigation bar is the same. Below the cluster name 'vagrant', there are links for 'Status' and 'Action History'. The 'Cluster Info' section contains a table with columns: Cluster name, Health, Hosts, Cores, Disk Capacity, and Memory Capacity. The 'vagrant' cluster is shown with Health 'Good', 1 Host, 2 Cores, 78.9 GB Disk Capacity, and 3.8 GB Memory Capacity. The 'Services' section contains a table with columns: Service, Roles, Roles Status, and Health. The services listed are 'YARN', 'MySQLCluster', and 'HOPS'. 'YARN' has roles '1 NodeManager' and '1 ResourceManager' with status '2 Started' and health 'Good'. 'MySQLCluster' has roles '1 mgmserver', '1 memcached', '1 ndb', and '1 mysqlid' with status '4 Started' and health 'Good'. 'HOPS' has roles '1 namenode' and '1 datanode' with status '2 Started' and health 'Good'.

Cluster name	Health	Hosts	Cores	Disk Capacity	Memory Capacity
vagrant	Good	1	2	78.9 GB	3.8 GB

Service	Roles	Roles Status	Health
YARN	1 NodeManager 1 ResourceManager	2 Started	Good
MySQLCluster	1 mgmserver 1 memcached 1 ndb 1 mysqlid	4 Started	Good
HOPS	1 namenode 1 datanode	2 Started	Good

In this new view, we can see that we have gone further inside the services the cluster consists of and here the user can identify the status of each of the services that are part of the current cluster instance. Selecting one of the services will show greater detail of information of the service. We will see how it looks like each view for each of the services that form the HOP. Note that in order for the graphs to appear, a user needs to configure the specific graph for the specific component, refer to the Edit Graph section found in this chapter.

YARN monitoring

If YARN is enabled in your cluster, you can get highly detailed information of YARN like the total amount of resource managers and node managers, and metrics of interest for YARN monitoring.

Figure 4.15. YARN Metrics

MySQL Cluster

You can get a highly detailed view of what is happening in MySQL cluster after deploying a Hop cluster. You can keep track of statistics of interest in order to keep the performance of your MySQL Cluster in good shape. If you select the MySQL you can obtain the following information if the graphs are configured accordingly, see Edit Graph section in this chapter.

Figure 4.20. MySQL overall graphs

We also offer additional functionality for users to maintain and manage the status of their MySQL cluster without the need to connecting directly to the machine. We provide an online terminal where users can execute mysql commands directly to the MySQL cluster without any delay.

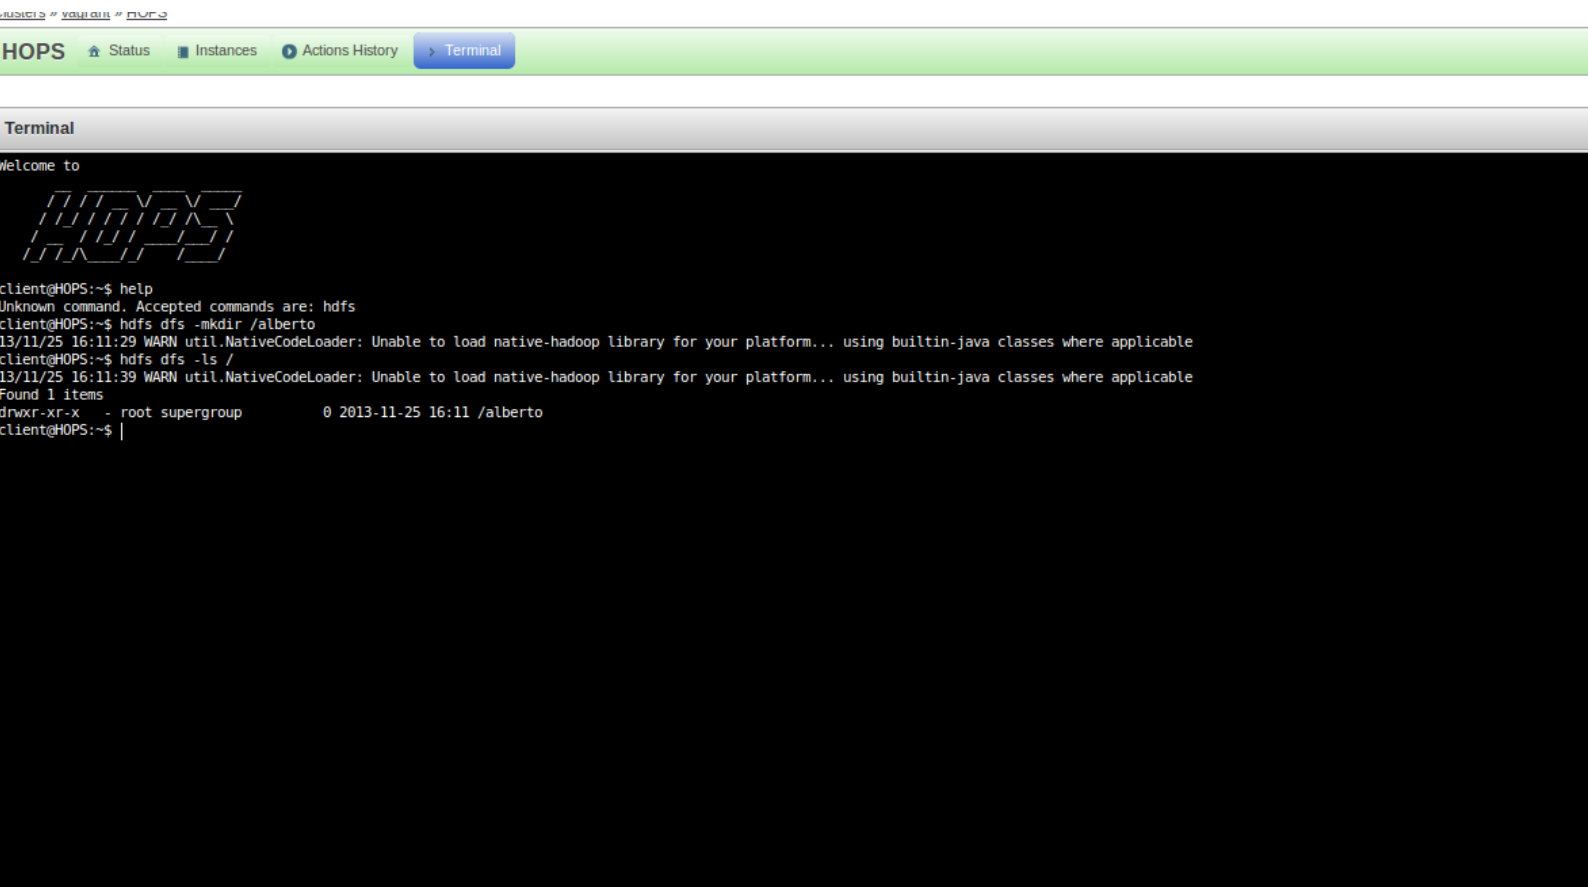

Figure 4.21. MySQL console

HOPS HDFS (Hadoop Filesystem)

You can get a highly detailed view of what is happening in the Hop file system after deploying a Hop cluster. You can keep track of statistics of interest in order to keep the performance of your Hop system in good shape. If you select the Hop option you can obtain information from the graphs previously configured in the Edit Graph section.

We also offer additional functionality for users to manage the file system without the need to connecting directly to the machine. We provide an online terminal where users can execute hdfs commands directly to the file system without any delay.

Chapter 5. Defining a Cluster

In this section, we describe the tools we offer in order to easily define and structure HOP clusters for their deployment through our orchestration architecture from the dashboard. In here, we will introduce you to our definition language to define clusters for cloud providers like Amazon EC2 and OpenStack or Baremetal clusters based on physical machines. With our cluster definition language, you will see that you will easily have a cluster deployed in a matter of minutes by making use of technologies like Chef that will be in charge of orchestrating the nodes while we provision them with Jclouds (in the case of a virtual environment) or a simple SSH client for your baremetal machines.

Cluster Definition Language

We will start first by presenting our Cluster Definition Language (CDL) with which you can defining your clusters with ease. In general, we handle the following abstractions:

- *Cluster*: A cluster is an entity that defines a whole system based on a heterogenous structure composed of multiple nodes. In most of the cases, we can classify the nodes into groups depending of the software they run. Also you need to provide the specific class tag of the type of cluster for our software to identify which type of cluster you want to deploy. To allow further customization of your cluster, we allow interesting options like the possibility of running chef recipes globally on all the nodes and open ports that you may want to be open.

Example 5.1. Defining Global Properties

```
!!se.kth.kthfsdashboard.virtualization.clusterparser.Cluster
##name of your cluster
name: test2
##enable install phase
installPhase: true
##global parameters
global:
##user defined recipes
  recipes:
    - ssh
    - chefClient
## extra ports you want to open
authorizePorts:
  - 3306
  - 4343
  - 3321
```

Git Repositories

If you want further customization, it is possible to fork our git repository and customize our chef recipes if you want to modify some parameters of our cluster. Also you can add your own recipes if you decide to launch other services on your code. Simply add this snippet of code under global parameters.

Example 5.2. Defining Git repository

```
git:
  user: Jim Dowling
  repository: https://ghetto.sics.se/jdowling/hops-chef.git
  key: notNull
```

- *Services:* We identify multiple services, in our case related to Hop platform. You can spread this services quite easily among different nodes just indicating that information when grouping them. Also you may indicate further services to be deployed on them.

```
service:
  - datanode
  - nodemanager
  number: 2
```

- *Provider:* In the case of defining a cluster to be deployed in a virtualized environment through an Amazon EC2 infrastructure or an OpenStack environment, you can give information of the image you want to use, the type of instance to request, login credentials in case you are using custom images.

Example 5.3. Defining Cloud Providers

```
provider:
  ##name of the provider, use aws-ec2 or openstack-nova
  name: aws-ec2
  ##if EC2 use a value to one of EC2 types, in OpenStack this is an id number
  ##type of instance you want to use
  instanceType: m1.large
  ## indicate the login user of the machine with sudo access, necessary for cu
  ## or openstack image
  loginUser: ubuntu
  ## image you want in EC2 or OpenStack
  image: eu-west-1/ami-35667941
  ##region of EC2 or project name in OpenStack
  region: eu-west-1
```

We will also see that the syntax differs depending if you are designing your cluster towards a virtualized environment or a physical environment. In the following sections, we will go through detailed examples for both types of clusters.

Structuring your Cluster:

Before using our tools, it is important that you have at least an idea of how you want to structure the services of our data platform among the different machines that will be part of the cluster. In our case, a fully functional cluster requires the following services deployed in different machines:

1. *MySQL Cluster:*

- *MySQL-NDB:* Your cluster should contain at least 2 instances of NDB

- *MySQL-MGM*: Your cluster should contain at least 1 instance of a Management Server.
- *MySQL-Mysqld*: Your cluster should contain at least 1 instance of a MySQL Server.

2. Hop

- *Namenode*: Your cluster should contain at least 2 namenode instances of our Hadoop Solution.
- *Datanode*: Your cluster should contain at least 2 datanode instances of our Hadoop Solution.

3. Data processing

- *ResourceManager*: Your cluster should contain at least 1 resource manager instances of YARN.
- *NodeManager*: Your cluster should contain at least 2 node manager instances of YARN.
- *Spark*: Your cluster should contain at least one instance of Spark if you want to do data processing through Spark to submit your jobs to the system.

Multiple Services per Node

The previous section gave a very simple overview of the components that are needed for a HOP cluster to work correctly. It is possible to allocate various services in one machine or group of machines as we will see in the following sections.

Now that we have a general perspective of how a cluster looks like, the next step is to identify the environment of your choice for the cluster you want to work with. In the following sections, we will describe how you can define the structure for virtualized cloud providers like Amazon EC2 and OpenStack or in a physical Baremetal environment.

Building your cluster:

In this section, we will explain through a couple of complete examples how to define your cluster for Amazon EC2, OpenStack or Baremetal. We will show you how to write your cluster from scratch using your own YAML file or you can use the available cluster wizard in order to generate your desired cluster.

Cluster in AWS

Lets imagine that we want to define a complete Hop which will contain a basic minimal setup. In this case we need 2 NDBs, 1 MGM and 1 Mysqld for the MySQL cluster, 2 namenode and 2 datanode for the Hadoop File System and in order to user Spark, a Spark instance with 1 resource manager and 2 node managers. How we could map the services using only 7 machines? A very simple configuration could be as follows:

Example 5.4. Full AWS Cluster Example

```
!!se.kth.kthfsdashboard.virtualization.clusterparser.Cluster
name: test2
provider:
  name: aws-ec2
  instanceType: m1.large
  loginUser: ubuntu
  image: eu-west-1/ami-35667941
  region: eu-west-1

##lists of groups, with the roles the nodes
##will have and open ports
nodes:
- service:
  - ndb
  number: 2

- service:
  - mgm
  number: 1

- service:
  - mysqld
  - namenode
  number: 1

- service:
  - namenode
  - resourcemanager
  number: 1

- service:
  - datanode
  - nodemanager
  - spark
  number: 2
```

With this configuration file, we will create 5 security groups which will have as a name the first service defined in the list. This will also open the ports for those security groups. It will install the defined services for each of the nodes in that specific group of nodes.

Cluster in OpenStack

Taking the previous case for Amazon EC2, we can easily the same cluster description using the same cluster definition file. In this the only section we need to change is related to the provider we want to use which in this case is OpenStack. The file will look as follows:

Example 5.5. Full OpenStack Example

```
!!se.kth.kthfsdashboard.virtualization.clusterparser.Cluster
name: nova
provider:
  name: openstack-nova
  instanceType: 7
  loginUser: ubuntu
  image: 0190f9c4-d64e-4412-ab88-4f9fd1d7c2e3
  region: RegionSICS

##lists of groups, with the roles the nodes
##will have and open ports
nodes:
  - service:
    - ndb
    number: 2

  - service:
    - mgm
    number: 1

  - service:
    - mysqld
    - namenode
    number: 1

  - service:
    - namenode
    - resourcemanager
    number: 1

  - service:
    - datanode
    - nodemanager
    - spark
    number: 2
```

With this configuration file, it is possible to deploy the same cluster we defined in Amazon EC2 without any major changes. You only need to change the provider specifications to match the details of your OpenStack Infrastructure.

Cluster on Baremetal Machines

How would we describe the same cluster for Amazon EC2 in a cluster of physical machines? In this case it is much simpler but you need to watch out for minor details like in this case the class tag needs to be different for this types of clusters as we will see. Also in this case, you need to provide the IP addresses of the machines to connect to. An example is as follows:

Example 5.6. Full Baremetal Example

```
!!se.kth.kthfsdashboard.virtualization.clusterparser.Baremetal
name: baremetal
loginUser: ubuntu
totalHosts: 7
nodes:
  - service: ndb
    number: 2
    hosts:
      - 10.20.0.8
      - 10.20.0.11

  - service: mgm
    number: 1
    hosts:
      - 10.20.0.6

  - service:
    - mysqld
    - namenode
    number: 1
    hosts:
      - 10.20.0.7

  - service:
    - namenode
    - resourcemanager
    number: 1
    hosts:
      - 10.20.0.12
      - 10.20.0.14

  - service:
    - datanode
    - nodemanager
    - spark
    number: 2
    hosts:
      - 10.20.0.16
      - 10.20.0.17
```

With this configuration file, it is possible to deploy the same cluster we defined in Amazon EC2 without any major changes. You only need to change the provider specifications to match the details of your OpenStack Infrastructure.

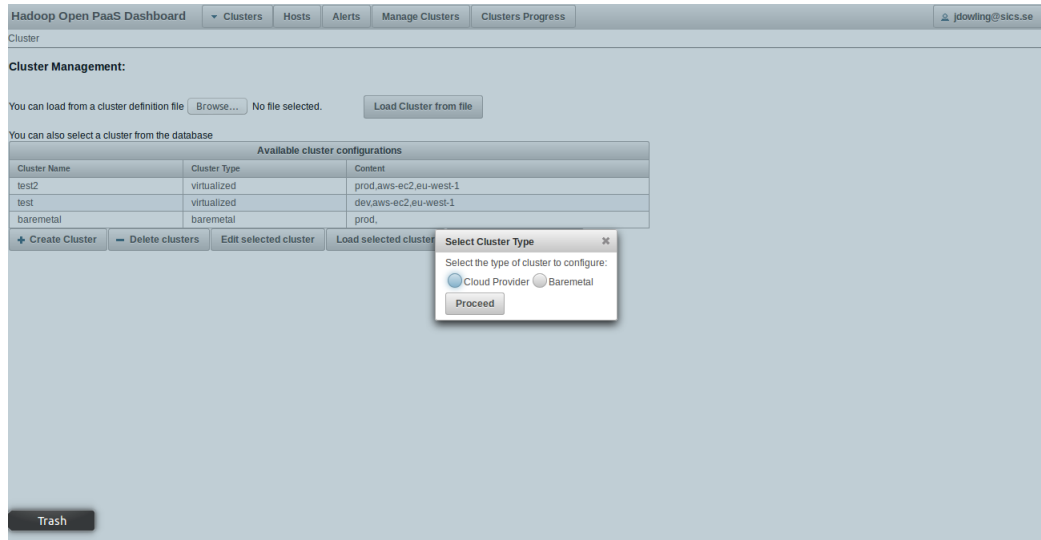

Cluster Generator on Dashboard

Apart of offering a mechanism where users can upload their clusters written in YAML to the system and later on deploy them, we also have a cluster wizard which allows the user to define a cluster step by step quite easily. To make use of this feature, follow these steps:

1. Go to the manage cluster section from the main bar in the dashboard. Select the create cluster option. Main Menu Bar → Manage Cluster → Create cluster
2. A dialog appears allowing you to select which type of cluster you want to use:

- *Virtualized*: Choose this option if you want to deploy a cluster in Amazon EC2 or OpenStack.
- *Baremetal*: Choose this option if you want to deploy a cluster in physical machines.

Figure 5.1. Select Cluster Type:

3. Selecting an option, will bring you to the cluster generator wizard. Here you can select the same options like if you were writing your own file from scratch. You will go through different phases.

Cluster Wizard → Common → Provider (not for Baremetal) → Groups → Confirmation

- *Common Section*: In this section, a form appears where you can select the following options:
 - a. *Name*: Name of the cluster
 - b. *Provider*: Select the type provider between Amazon EC2 or OpenStack, this option is available if we create a virtualized cluster.
 - c. *Git parameters*: Git repository section where you can specify as an option your own git repository based on our code. This way you can customize our recipes or even add your own.
 - d. *Global Recipes*: You can specify chef recipes that you want to execute in all the nodes
 - e. *Global Ports*: Additional Ports to open for your cluster, this option is only available for virtualized clusters.

- *Provider Section:* This form enables you to define the parameters for OpenStack or Amazon EC2. Some values appear by default in the case of Amazon EC2 where you can use them directly if you want.

- a. *Instance Type*: The type of instance you want to use in Amazon EC2 or in OpenStack. Note that in OpenStack we use the id number of the type of instance, not the name.
- b. *Image*: The name of the image we want to use the in Amazon EC2 or in OpenStack
- c. *Login user*: Here you include the user name with sudo access to access the instances in Amazon EC2 or OpenStack. Note that this value is necessary if you use a custom AMI in Amazon EC2 or using OpenStack.
- d. *Region*: Here you include the region you want to deploy in Amazon EC2 or the project to use in your OpenStack infrastructure.

Figure 5.4. Cluster Provider Options:

- *Group Section*: In this section you can specify the group of nodes for you cluster with the their services and ip addresses (if you are deploying a baremetal cluster)
 - a. *Main Service*: The main service you want to deploy in this group of nodes
 - b. *Bittorrent Support*: If you want to enable bittorrent sync of binaries from the dashboard.
 - c. *Number of nodes*: Number of nodes that will contain the same set of services.
 - d. *Extra Services*: Other services you may want to run which can be also your own services.
 - e. *ChefAttributes*: In this section, you would include a chef json which will contain the attributes you may want to override from your recipes.
 - f. *Ports*: Extra ports that you may want to enable in that group, in this case this only affect virtualized clusters.
 - g. *Hosts*: List of hosts IP addresses for the nodes that will be part of this group of nodes. In this case this option is only available for Baremetal clusters.

- *Confirmation Section:* In this section you will see a summary of the details of your cluster file. When you press the submit button, your cluster file will be stored in the dashboard and it will proceed to the cluster launcher.

Figure 5.7. Confirmation:

The screenshot shows a web-based configuration wizard with four tabs: 'Common', 'Provider', 'Groups', and 'Confirmation'. The 'Confirmation' tab is active. Below the tabs is a section titled 'Confirmation' with a sub-section 'General Details:' containing the following fields:

Name:	test2
Environment:	prod
Install Phase:	false
Authorize Ports:	[3306, 4343, 3321]
Git user:	Jim Dowling
Git repository:	https://ghetto.sics.se/jdowling/kthfs-pantry.git
Git key:	notNull

Below the 'General Details' section are two collapsed sections: 'Provider Details:' and 'Nodes:'. At the bottom of the form are two buttons: 'Submit' and '← Back'.

Wrap up

To summarize this section, in here we have seen the main building blocks that we need to define a cluster using our cluster domain specific language. We also explained how you can define your clusters by writing your own cluster file through multiple examples and also showed an alternative way of defining cluster through the cluster generator wizard which is accessible from the dashboard.

Chapter 6. Launching a Cluster

Installation on AWS

In this section, we will explain further steps that are required to deploy a whole functional cluster running our data platform through the dashboard. Also we refer to recommendations and aspects you should consider before deploying a cluster.

Pre-requisites:

Before starting, make sure that you have access to a functional and running Dashboard in a virtual machine in an accessible Amazon EC2 region. If you have not done so, please refer back to the section Getting Started for further information.

Requirements:

In order to install and deploy a cluster, you need to define before the structure of the cluster which includes specifying the number of machines to create in EC2 with the specific instance type with the specific software. This can be done using a cluster definition file that can be done from scratch or using the embedded wizard available on the dashboard. Further information about describing a cluster can be found on the cluster configuration section. Before continuing make sure that you have the following.

- Cluster definition for EC2 (see related section) in a file or loaded from the dashboard database.
- Amazon EC2 credentials to deploy the cluster in Amazon, configured in the dashboard. In order to do it, select the option setup credentials found in your user icon to specify the EC2 credentials to be used by the dashboard.

Additional dashboard credentials

It is possible to include other options when deploying a EC2 cluster, for example; for maintenance purposes you might want to authorize extra public keys to the virtual machines. This is possible to set in the credential section of the dashboard

Launching the cluster

Once we have the dashboard configured with the Amazon EC2 credentials, you can proceed to launch a cluster:

1. Select the manage cluster option available in the dashboard.

Main Menu Bar → Manage Cluster → Load File

2. In this new view, you can manage available clusters that you may have defined previously. You can select a previous cluster, create a new one with the only wizard or load a cluster from a cluster definition file. For further information on managing cluster files, see the cluster configuration section. To continue, select a cluster from the table or load a cluster from a file.
3. The file is loaded and the launcher view should appear. Here you can view the contents of the cluster to be deployed before launch.
4. Pressing the start cluster will start the deployment process. A status bar will appear giving information of the current process. Also a progress table on the background will be generated with information of the configuration state of the nodes. The process is long and it depends on the number of nodes you deploy. On average, for 8 nodes it takes around 35 minutes.

Error Nodes

It is possible that some nodes will have issues during the deployment of our software (package configuration problem, erratic behaviour) which in this case our system will detect and will retry to relaunch the software on that specific machine automatically. The maximum number of retries specified for each node is 5, after that; the node will be tagged as an error node and it is possible to do a manual retry after the whole process has finished.

5. When the process completes, it will take you back to the progress view where you can see details of the cluster deployment. If nodes failed, you can select those nodes and try to recover them using the retry nodes option.

Retrying Nodes

Retrying node is an option that helps bringing back nodes that had minor issues when installing packages, were to slow to finish the configuration phase or the default number of retries we use were not enough. It will not bring back nodes which had a critical configuration failure, which in this case it will be necessary to log in directly through SSH to the specific machine in order to fix it.

Congratulations, if everything went okay; you have successfully deployed a complete cluster ready to use!

Installation on OpenStack

In this section, we will explain further steps that are required to deploy a whole functional cluster running our data platform through the dashboard. Also we refer to recommendations and aspects you should consider before deploying a cluster in OpenStack.

OpenStack Deployment

Note please that this option is currently in development phase and from our tests we managed to deploy functional testing clusters. Still due to issues we encountered during our tests in our personal OpenStack, we cannot guarantee the same level of performance as deploying for example a cluster in EC2. This is due to the fact that our deployment system depends greatly on how effectively OpenStack behaves with your hardware and so unexpected behaviour might take place. If you have a very good OpenStack infrastructure, we invite you to test it.

Pre-requisites:

Before starting, make sure that you have access to a functional and running Dashboard in a virtual machine accessible from your OpenStack Infrastructure. If you have not done so, please refer back to the section Getting Started for further information.

Requirements:

In order to install and deploy a cluster, you need to define before the structure of the cluster which includes specifying the number of machines to create in OpenStack with the specific instance type with the specific software. This can be done using a cluster definition file that can be done from scratch or using the embedded wizard available on the dashboard. Further information about describing a cluster can be found on the cluster configuration section. Before continuing make sure that you have the following.

- Cluster definition for OpenStack (see related section) in a file or loaded from the dashboard database.

- OpenStack credentials to deploy the cluster your OpenStack infrastructure, configured in the dashboard. In order to do it, select the option setup credentials found in you user icon to specify the OpenStack credentials to be used by the dashboard.

Additional dashboard credentials

It is possible to include other options when deploying a OpenStack cluster, for example; for maintainance purposes you might want to authorize extra public keys to the virtual machines. This is possible to set in the credential section of the dashboard

Launching the cluster

Once we have the dashboard configured with the OpenStack credentials, you can proceed to launch a cluster:

1. Select the manage cluster option available in the dashboard.

Main Menu Bar → Manage Cluster → Load File

2. In this new view, you can manage available clusters that you may have defined previously. You can select a previous cluster, create a new one with the only wizard or load a cluster from a cluster definition file. For further information on managing cluster files, see the cluster configuration section. To continue, select a cluster from the table or load a cluster from a file.
3. The file is loaded and the launcher view should appear. Here you can view the contents of the cluster to be deployed before launch.
4. Pressing the start cluster will start the deployment process. A status bar will appear giving information of the current process. Also a progress table on the background will be generated with information of the configuration state of the nodes. The process is long and it depends on the number of nodes you deploy. On average, for 8 nodes it takes around 35 minutes.

Error Nodes

It is possible that some nodes will have issues during the deployment of our software (package configuration problem, erratic behaviour) which in this case our system will detect and will retry to relaunch the software on that specific machine automatically. The maximum number of retries specified for each node is 5, after that; the node will be tagged as an error node and it is possible to do a manual retry after the whole process has finished.

5. When the process completes, it will take you back to the progress view where you can see details of the cluster deployment. If nodes failed, you can select those nodes and try to recover them using the retry nodes option.

Retrying Nodes

Retrying node is an option that helps bringing back nodes that had minor issues when installing packages, were to slow to finish the configuration phase or the default number of retries we use were not enough. It will not bring back nodes which had a critical configuration failure, which in this case it will be necessary to log in directly through SSH to the specific machine in order to fix it.

Congratulations, if everything went okay; you have succesfully deployed a complete cluster ready to use!

Installation on Baremetal Machines

In this section, we explain the steps that are required through the dashboard to deploy our data platform on a cluster of hosts running the linux operating system.

Pre-requisites:

Before starting, make sure that you have access to a functional and running Dashboard in a host which you can access via a browser. If you have not done so, please refer back to the section Getting Started for further information.

Requirements:

In order to install and deploy a cluster, you first need to specify the set of ip addresses for the hosts where the and the specific software. This can be done using a cluster definition file that can be done from scratch or using the embedded wizard available on the dashboard. Further information about describing a cluster can be found on the cluster configuration section. Before continuing make sure that you have the following.

- Cluster definition for a baremetal cluter (see related section) in a file or loaded from the dashboard database.
- Credentials to connect to your physical machine, this means a user name with sudo access and the private key to SSH the machines.

Launching the cluster

Once we have the dashboard configured with the physical machines credentials, you can proceed to launch a cluster:

1. Select the manage cluster option available in the dashboard.

Main Menu Bar → Manage Cluster → Load File

2. In this new view, you can manage available clusters that you may have defined previously. You can select a previous cluster, create a new one with the only wizard or load a cluster from a cluster definition file. For further information on managing cluster files, see the cluster configuration section. To continue, select a cluster from the table or load a cluster from a file.
3. The file is loaded and the launcher view should appear. Here you can view the contents of the cluster to be deployed before launch.
4. Pressing the start cluster will start the deployment process. A status bar will appear giving information of the current process. Also a progress table on the background will be generated with information of the configuration state of the nodes. The process is long and it depends on the number of nodes you deploy. On average, for 8 nodes it takes around 35 minutes.

Error Nodes

It is possible that some nodes will have issues during the deployment of our software (package configuration problem, erratic behaviour) which in this case our system will detect and will retry to relaunch the software on that specific machine automatically. The maximum number of retries specified for each node is 5, after that; the node will be tagged as an error node and it is possible to do a manual retry after the whole process has finished.

5. When the process completes, it will take you back to the progress view where you can see details of the cluster deployment. If nodes failed, you can select those nodes and try to recover them using the retry nodes option.

Retrying Nodes

Retrying node is an option that helps bringing back nodes that had minor issues when installing packages, were to slow to finish the configuration phase or the default number

of retries we use were not enough. It will not bring back nodes which had a critical configuration failure, which in this case it will be necessary to log in directly through SSH to the specific machine in order to fix it.

Congratulations, if everything went okay you have successfully deployed a cluster that is ready to use!

Chapter 7. Configuring HDFS

We introduce a few new configuration parameters to HDFS, due to our support for multiple NameNodes and use of MySQL Cluster for metadata storage. These parameters are specified in *hdfs-site.xml*. The configuration parameters listed below are additional to the configuration parameters for vanilla HDFS [<http://hadoop.apache.org/docs/current/hadoop-project-dist/hadoop-hdfs/hdfs-default.xml>].

HDFS Configuration Parameters not used

We have replaced HDFS 2.x's Primary-Secondary Replication model with shared atomic transactional memory. This means that we no longer use the parameters in HDFS that are based on the (eventually consistent) replication of *edit log entries* from the Primary NameNode to the Secondary NameNode using a set of quorum-based replication servers. Here are the parameters that are not used in the HOP version of HDFS 2.x:

- *dfs.namenode.secondary.**: None of the secondary NameNode attributes are used.
- *dfs.namenode.checkpoint.**: None of the checkpoint attributes are used.
- *dfs.image.**: None of the FSImage attributes are used.
- *dfs.journalnode.**: None of the hadoop's journaling attributes are used.
- *dfs.ha.**: None of the hadoop high availability attributes are used.
- *dfs.namenode.num.extra.edits.**: None of the edit logs attributes are used.
- *dfs.namenode.name.dir.**: FSImage is not supported anymore.
- *dfs.namenode.edits.**: None of the edit log attributes are used.
- *dfs.namenode.shared.edits.**: None of the edit log attributes are used.

Additional HDFS Configuration Parameters

- *dfs.storage.type*: In HOP all the NameNodes in the system are stateless. All the file system metadata is stored in a relational database. We have chosen MySQL NDB Cluster for its high performance and availability for the storage of the metadata. However the metadata can be stored in any relational database. Default value is this parameter is 'clusterj'. By default HOPS uses ClusterJ libraries to connect to MySQL NDB Cluster. Later we will provide support of other DBMSs.
- *dfs.dbconnector.string*: Host name of management server of MySQL NDB Cluster.
- *dfs.dbconnector.database*: Name of the database that contains the metadata tables.
- *dfs.dbconnector.num-session-factories*: This is the number of connections that are created in the ClusterJ connection pool. If it is set to 1 then all the sessions share the same connection; all requests for a SessionFactory with the same connect string and database will share a single SessionFactory. A setting of 0 disables pooling; each request for a SessionFactory will receive its own unique SessionFactory. We set the default value of this parameter to 3.
- *dfs.storage.mysql.user*: A valid user name to access MySQL Server. For higher performance we use MySQL Server to perform aggregate queries on the file system metadata.
- *dfs.storage.mysql.user.password*: MySQL user password
- *dfs.storage.mysql.port*: MySQL Server port. If not specified then default value of 3306 is chosen.

- *dfs.quota.enabled*: Using this parameter quota can be en/disabled. By default quota is enabled.
- *dfs.namenodes.rpc.address*: HOP support multiple active NameNodes. A client can send a RPC request to any of the active NameNodes. This parameter specifies a list of active NameNodes in the system. The list has following format [ip:port, ip:port, ...]. It is not necessary that this list contain all the active NameNodes in the system. Single valid reference to an active NameNode is sufficient. At the time of startup the client will obtain the updated list of all the NameNodes in the system from the given NameNode. If this list is empty then the client will connect to 'fs.default.name'.
- *dfs.namenode.selector-policy*: For a RPC call client will choose an active NameNode based on the following policies.

1. ROUND_ROBIN

2. RANDOM

By default NameNode selection policy is set of ROUND_ROBIN

- *dfs.leader.check.interval*: One of the active NameNodes is chosen as a leader to perform housekeeping operations. All NameNodes periodically send a HeartBeat and check for changes in the membership of the NameNodes. By default the HeartBeat is sent after every second. Increasing the time interval would lead to slow failure detection.
- *dfs.leader.missed.hb*: This property specifies when a NameNode is declared dead. By default a NameNode is declared dead if it misses a HeatBeat. Higher values of this property would lead to slow failure detection.
- *dfs.block.pool.id*: Due to shared state among the NameNodes, HOP only support one block pool. Set this property to set a custom value for block pool. Default block pood id is HOP_BLOCK_POOL_123.
- *dfs.name.space.id*: Due to shared state among NameNodes, HOP only support one name space. Set this property to set a custom value for name space. Default name space id is 911 :)
- *dfs.clinet.max.retires.on.failure*: The client will retry the RPC call if the RPC fails due to the failure of the NameNode. This property specifies how many times the client would retry the RPC before throwing an exception. This property is directly related to number of expected simultaneous failures of NameNodes. Set this value to '1' in case of low failure rates such as one dead NameNode at any given time. It is recommended that this property must be set to value ≥ 1 .
- *dsf.client.max.random.wait.on.retry*: A RPC can fail because of many factors such as NameNode failure, network congestion etc. Changes in the membership of NameNodes can lead to contention on the remaining NameNodes. In order to avoid contention on the remaining NameNodes in the system the client would randomly wait between [0,MAX_VALUE] ms before retrying the RPC. This property specifies MAX_VALUE; by default it is set to 1000 ms.
- *dsf.client.refresh.namenode.list*: All clients periodically refresh their view of active NameNodes in the system. By default after every minute the client checks for changes in the membership of the NameNodes. Higher values can be chosen for scenarios where the membership does not change frequently.
